Inflation Forecasting:
A Comparative Study of Pakistan

(using ARIMA, Ridge, LASSO, Elastic Net)

Islamabad, Pakistan

Introduction

Inflation is a fundamental economic indicator that reflects changes in the general price levels of goods and services, significantly influencing purchasing power and economic decision making. For a developing country such as Pakistan, forecasting inflation is essential for effective policy planning, ensuring economic stability, and guiding fiscal and monetary actions.

Pakistan's economic environment is shaped by a mix of agricultural and industrial sectors, and over the years, it has experienced volatile inflation rates due to various internal and external factors, including political instability, fiscal deficits, global oil prices, and fluctuations in exchange rates. These complexities require advanced forecasting methods to better understand and anticipate the dynamics of inflation.

Accurate inflation forecasting plays a key role in designing effective *monetary and fiscal policies*. Policymakers, especially central banks, rely on inflation projections to make timely decisions about interest rates, liquidity management, and inflation targeting. Given the dynamic nature of inflation, traditional econometric models often face challenges in capturing nonlinear relationships and structural breaks. This project addresses that gap by employing a variety of forecasting models, including **ARIMA, Ridge Regression, LASSO, and Elastic Net**, to assess and compare their effectiveness in forecasting inflation in Pakistan from **1990 to 2025** using **annual data**.

The dependent variable in this study is the Consumer Price Index (CPI)-based **inflation rate**, while the initial set of independent variables was selected based on established economic theory and supported by literature. These variables include GDP, Broad Money Growth, Tariff Rate, Exchange Rate, Oil Prices, External Debt, Unemployment, and others. However, through preliminary regression analysis and significance testing, the final model focuses on five key variables that showed strong explanatory power:

- **Tariff Rate**
- **Unemployment Rate**
- **Exchange Rate (PKR/USD)**
- **Brent Crude Oil Price**
- **External Debt (% of GNI)**

These variables were chosen due to their theoretical relevance and observed statistical significance in influencing inflation in the Pakistani context. For instance, higher tariff rates and oil prices can contribute to *cost-push inflation*, while a depreciating exchange rate often fuels *imported inflation*. Similarly, unemployment and external debt influence inflation through both demand-side and currency-based channels.

The objective of this project is to develop reliable inflation forecasting models based on these variables, compare their predictive accuracy, and provide insights into which model performs best for Pakistan. The results can offer valuable guidance for policy analysts, economists, and decision-makers in anticipating inflation trends and planning interventions accordingly.

Literature Review

1. Inflation Forecasting Models

Inflation forecasting has long been a topic of interest for economists, as it plays a crucial role in shaping monetary policy. Various econometric models have been employed to predict inflation, with mixed success depending on the context and data available.

Gali, J., & Gertler, M. (2007): This study examines the role of inflation forecasting in monetary policy decisions, with a focus on time-series models such as ARIMA and VAR (Vector Autoregression). The authors emphasize that effective forecasting helps central banks manage inflation expectations, essential for stabilizing economies. In volatile economies, the need for more sophisticated models that capture external shocks and nonlinear relationships is critical.

Stock, J. H., & Watson, M. W. (2007): Stock and Watson's work explores a hybrid approach combining time-series models like ARIMA with macroeconomic variables to improve inflation predictions. The study shows that adding external variables, such as exchange rates and oil prices, enhances the accuracy of forecasts, particularly in economies subject to external shocks.

Clark, T. E., & McCracken, M. W. (2009): This paper discusses using advanced econometric techniques, such as Ridge Regression and LASSO, for forecasting inflation. The authors find that regularization methods like these improve forecasting by reducing multicollinearity, which is a common problem in large datasets with highly correlated variables.

2. Key Drivers of Inflation in Developing Economies

Understanding the key drivers of inflation is crucial for building effective forecasting models. In developing countries like Pakistan, external shocks such as oil prices, exchange rates, and tariff rates, as well as internal factors like unemployment and fiscal deficits, play significant roles in determining inflation.

Chaudhry, A. S., & Niazi, G. (2011): This study investigates the effects of external debt, oil prices, and exchange rates on inflation in Pakistan. The authors conclude that global oil price fluctuations significantly influence inflation, demonstrating the importance of including oil prices in forecasting models.

Khan, M. A., & Schimmelpfennig, D. (2006): The paper explores how exchange rate depreciation impacts inflation in Pakistan. A weaker Pakistani rupee leads to higher import costs, which, in turn, contribute to higher inflation. This relationship underscores the need to include the exchange rate as a predictor in forecasting models.

Ahmed, R., & Malik, A. (2013): This study examines the role of tariff rates in driving inflation in Pakistan. The authors find that increasing tariffs lead to higher costs for producers, which are passed on to consumers as higher prices, highlighting tariff rates as an important cost-push inflationary factor in the country.

3. Econometric Models for Inflation Forecasting

Various econometric models have been utilized to forecast inflation, each with its strengths and limitations. In particular, traditional methods like ARIMA are widely used but may not capture nonlinear relationships in data.

Bernanke, B. S., Gertler, M., & Watson, M. W. (1997): This paper provides an overview of the application of ARIMA and VAR models in forecasting inflation. The authors argue that while ARIMA models work well for short-term predictions, they often fail to capture the complexities introduced by structural changes in the economy.

Lee, J., Phelps, D., & Han, Y. (2012): This study explores the use of LASSO regression for forecasting inflation, highlighting how LASSO can enhance model performance by selecting the most relevant variables and improving model accuracy in the presence of many potential predictors.

Suneja, R., & Gupta, R. (2015): Suneja and Gupta discuss the Elastic Net model, which combines elements of Ridge Regression and LASSO to address the limitations of each. They show that Elastic Net outperforms traditional methods in predicting inflation, especially in economies with highly correlated variables.

4. Forecasting in the Context of Pakistan

Specific studies on inflation forecasting in Pakistan reveal unique challenges faced by the country, including political instability, exchange rate volatility, and global economic conditions.

Malik, A., & Rehman, H. (2010): This study investigates Pakistan's inflation trends over several decades, identifying key factors such as oil price shocks, fiscal deficits, and exchange rate fluctuations. The authors highlight the limitations of traditional econometric models and suggest that incorporating more dynamic models could improve forecasting accuracy.

Qureshi, M. A., & Majeed, M. (2009): This paper explores the relationship between unemployment and inflation in Pakistan, using econometric models to show how both demand-side and supply-side factors interact to affect inflation. The study suggests that understanding this interaction is critical for improving inflation forecasts in Pakistan.

Data and Variable Description:

This study employs a comprehensive time-series dataset (1990–2023) to model and forecast inflation in Pakistan using key macroeconomic indicators. These variables are selected based on economic theory and empirical evidence regarding their influence on inflation, particularly in developing economies like Pakistan. **Inflation Rate**

- **Description: Annual percentage change in Consumer Price Index (CPI).**
- **Source: World Development Indicators, Data Bank.**
- **Type: Dependent variable**

Table 1: Independent Variables and Their Effects on Inflation

Variable	**Description**	**Expected Effect on Inflation**
GDP (Gross Domestic Product)	Total annual economic output of a country.	Positive — Higher GDP increases aggregate demand, causing demand-pull inflation.
Tariff Rate, Applied, Weighted Mean (%)	Average tariff rate on imports.	Positive — Increases cost of imports, leading to imported inflation.
Broad Money Growth (Annual %)	Yearly growth in total money supply.	Positive — More money supply increases purchasing power, driving inflation.
Unemployment (% of Labor Force)	Proportion of unemployed labor force.	Negative — High unemployment reduces demand, suppressing inflation.
Official Exchange Rate (PKR/USD)	Local currency per US dollar (period average).	Positive — Depreciation increases import costs, raising domestic prices.
Brent Crude Oil (USD/barrel)	Benchmark for international oil prices.	Positive — Rising oil prices raise production and transport costs (cost-push inflation).
External Debt Stocks (% of GNI)	Total external debt relative to Gross National Income.	Positive — May cause inflation via currency depreciation or debt monetization.
Ln of Goods Exports (US$)	Natural log of total goods exports.	Mixed — May reduce domestic supply (↑ prices), or boost income and demand.
Ln of Use of IMF Credit (US$)	Natural log of IMF borrowings.	Positive — May lead to inflation if linked with expansionary fiscal policies.
ASINH of Portfolio Equity Inflows (US$)	Transformed net foreign portfolio equity inflows.	Positive — Boosts liquidity and demand, potentially increasing inflation.
Use of IMF Credit (US$)	Total IMF disbursements to the country.	Positive — Similar to above; can increase money supply and demand.
Portfolio Equity, Net Inflows (US$)	Net foreign investment in equity markets.	Positive — Sustained inflows raise demand for goods/services, leading to inflation.
Goods Exports (US$)	Total value of exported goods.	Mixed — May reduce supply (↑ prices) or increase income-driven demand.

Variable Selection

After conducting an extensive literature review and performing statistical significance testing, several variables were evaluated for their impact on inflation. Based on empirical evidence and model diagnostics, some variables were dropped due to insignificance or multicollinearity. The final set of selected independent variables for the analysis includes:

- Tariff Rate (Applied, Weighted Mean %)
- Unemployment Rate (% of Total Labor Force)
- Official Exchange Rate (PKR/USD)
- Brent Crude Oil Price (USD/barrel)
- External Debt Stocks (% of GNI)

```
lm(formula = Inflation ~ `Tariff Rate` + Unemployment + `Exchange Rate` +
    `Brent Oil` + `External Debt`, data = data)

The data presents summary statistics for several key economic variables:

Inflation

- **Range**: 2.529% (minimum) to 30.768% (maximum)
- **Median**: 9.503%
- **Mean**: 9.967%

This indicates moderate to high inflation overall, with some economies experiencing very high inflation rates above 30%.

Tariff Rate

- **Range**: 7.610% (minimum) to 44.940% (maximum)
- **Median**: 11.155%
- **Mean**: 19.707%

The third quartile at 27.520% suggests a right-skewed distribution, with some countries implementing significantly higher tariffs.

Unemployment

- **Range**: 0.398% (minimum) to 26.338% (maximum)
- **Median**: 0.640%
- **Mean**: 2.057%

This shows most economies have relatively low unemployment, but some outliers face severe unemployment challenges.

Exchange Rate

- **Range**: 21.71 to 280.36
- **Median**: 66.17
- **Mean**: 93.78

The wide range indicates significant currency value differences across the dataset.

Brent Oil

- **Range**: 13.13 to 112.01 (likely USD per barrel)
- **Median**: 53.85
- **Mean**: 53.51

The close median and mean suggest a fairly symmetric distribution of oil prices.

External Debt

- **Range**: 23.28 to 55.90 (likely as % of GDP)
- **Median**: 34.31
- **Mean**: 36.65

Most economies have external debt between 27.38% (1st quartile) and 48.69% (3rd quartile) of GDP.

Group Classification

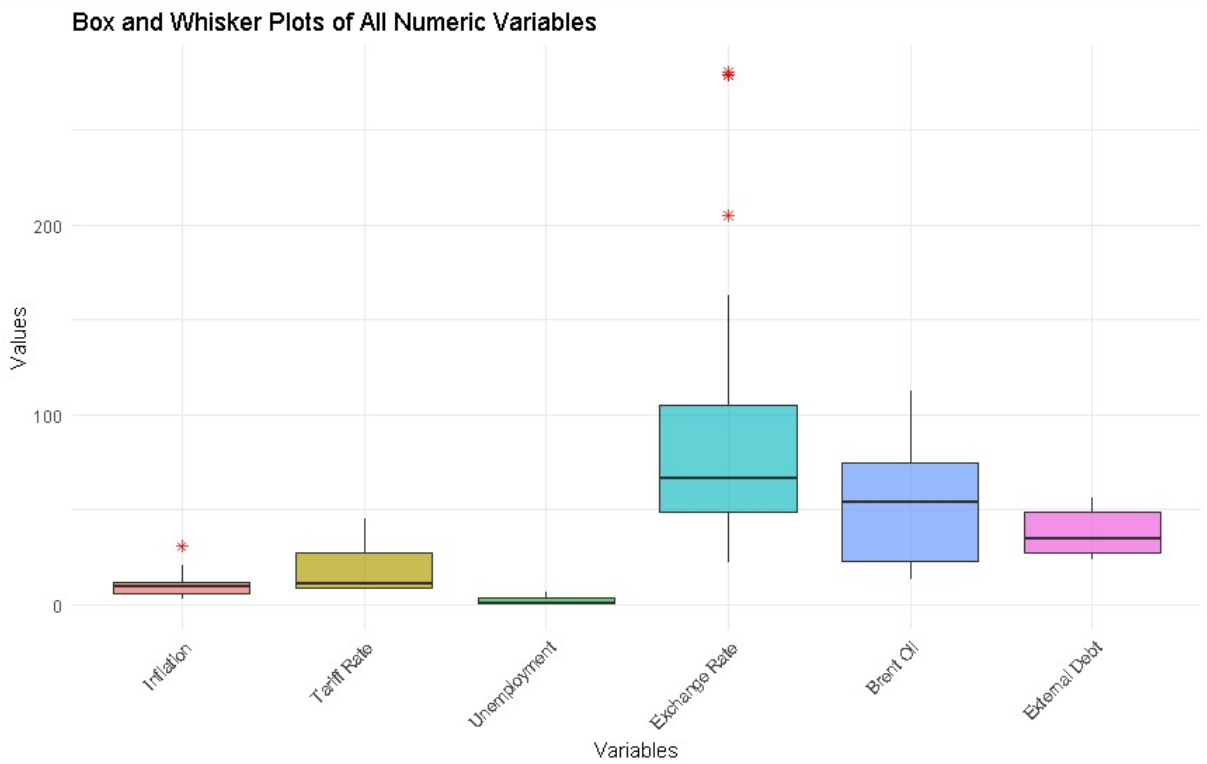
- **Low**: 28 entities
- **Medium**: 65 entities
- **High**: 1 entity

Key Observations

- **Economic Disparities**: The wide ranges across all variables indicate significant economic differences between the entities in the dataset.
- **Inflation and Tariff Skew**: Both inflation and tariff rates show right-skewed distributions (means higher than medians), suggesting a few countries with extremely high values.
- **Unemployment Distribution**: The large difference between mean (2.057%) and median (0.640%) unemployment suggests outliers with very high unemployment rates.

- **Exchange Rate Variation**: The substantial gap between the 3rd quartile (104.94) and maximum (280.36) indicates a few countries with significantly devalued currencies.
- **Group Classification**: The data classifies most entities in the "Medium" category (65), with a significant number in "Low" (28), but only one entity classified as "High."

Analysis Of Box and Whisker Plots for Economic Variables:



This box and whisker plot visualization provides important insights into the distribution of six economic variables from the dataset:

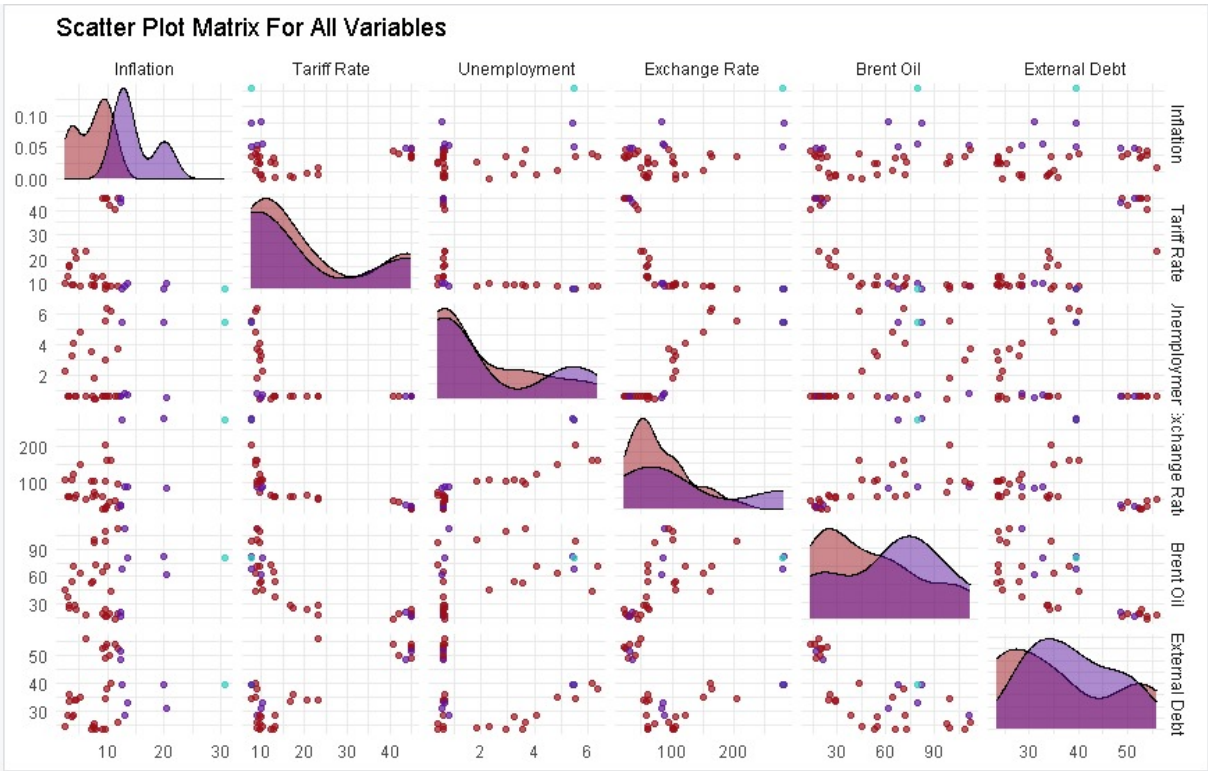
- **Inflation**
  - Relatively narrow box centered around 10%
  - At least one significant outlier around 30%
  - Mostly clustered values, indicating similar inflation across economies
  - Slight right skew due to high outliers

- **Tariff Rate**
  - Moderate spread: 10% to 25%
  - Wider spread than inflation → more variation
  - Whiskers from 5% to 45%
  - Median in lower half → right-skewed
- **Unemployment**
  - Very narrow range near 0–5%
  - Most compressed variable → low unemployment in most cases
  - No visible extreme outliers
- **Exchange Rate**
  - Wide IQR (50–100)
  - Two extreme outliers at 200 and 250
  - Highest variability of all indicators
  - Long upper whisker → major differences across economies
- **Brent Oil**
  - Moderate IQR (25–70)
  - Fairly symmetric distribution
  - Upper whisker up to 110
- **External Debt**
  - Narrow IQR (30–45)
  - Consistent values across dataset
  - Few outliers → most stable indicator

Key Insights

- **Variance:** Exchange Rate shows the most, Unemployment the least
- **Outliers:** Exchange Rate and Inflation have most significant ones
- **Distributions:**
  - Exchange Rate and Tariff Rate are right-skewed
  - External Debt is nearly symmetric
  - Unemployment is compressed near the low end
- **Policy Implications:** Exchange Rate and Tariff Rate variability may reflect policy diversity, while stable debt levels suggest common borrowing patterns
- **Economic Stability:** High outliers in Inflation and Exchange Rate may indicate instability in certain economies

Analysis For Scatter Plots Matrix for Economic Variables:



The scatter plot matrix provides insights into relationships between six economic variables: Inflation, Tariff Rate, Unemployment, Exchange Rate, Brent Oil, and External Debt.

Key Relationships Between Variables

Inflation

- vs. Tariff Rate: Slight positive correlation
- vs. Exchange Rate: Moderate positive correlation
- vs. Brent Oil: Weak positive relationship
- vs. External Debt: Minimal visible correlation

Tariff Rate

- vs. Unemployment: Limited correlation, slight clustering
- vs. Exchange Rate: Moderate positive correlation
- vs. External Debt: Weak negative relationship

Unemployment

- vs. Exchange Rate: Weak positive correlation
- vs. Brent Oil: No strong pattern
- vs. External Debt: Very limited correlation

Exchange Rate

- vs. Brent Oil: Limited correlation with clustering
- vs. External Debt: Weak relationship, high scatter

Brent Oil vs. External Debt: Minimal correlation

Distribution Patterns (Diagonal of Matrix)

- **Inflation:** Right-skewed, mostly <10%
- **Tariff Rate:** Bimodal (peaks at 10% and 20–25%)
- **Unemployment:** Strong right skew, values mostly <2%
- **Exchange Rate:** Right-skewed, extends beyond 200
- **Brent Oil:** Symmetric, centered 50–60
- **External Debt:** Slight left skew, centered 35–45

Notable Observations

- **Clustering Patterns:** Especially in Exchange Rate plots
- **Outliers:** Common, especially for Exchange Rate
- **Policy Implications:**
  - Higher inflation linked with protective tariff policies
  - Exchange Rate ties closely with other economic factors
- **Variable Independence:** Some pairs (e.g., Debt vs. Oil) show minimal interaction
- **Multimodal Distributions:** Especially in Tariff Rate
- **Concentration Points:** Unemployment heavily concentrated at low levels

Estimation of Models:

ARIMA (AutoRegressive Integrated Moving Average)

ARIMA is a time series forecasting model that combines three components:

- **Autoregression (AR):** Utilizes the dependence between an observation and a number of lagged observations.
- **Integrated (I):** Applies differencing of observations to make the time series stationary.
- **Moving Average (MA):** Uses dependency between an observation and a residual error from a moving average model.

It is primarily used for univariate time series forecasting based on historical data.

Ridge Regression

Ridge regression is a type of linear regression that includes **L2 regularization**, which penalizes large coefficient values:

- Helps reduce overfitting.
- Useful when there are multiple correlated predictors.

LASSO (Least Absolute Shrinkage and Selection Operator)

LASSO is another type of linear regression that includes **L1 regularization**. It:

- Penalizes large coefficients.
- Performs variable selection by shrinking some coefficients to exactly zero.

Elastic Net

Elastic Net combines both **L1 (LASSO)** and **L2 (Ridge)** regularization:

- Provides feature selection and regularization.
- Especially useful when there are many correlated features.

Model Equations

ARIMA (p,d,q)

$$Y_t = \mu + \sum_{i=1}^{p} \phi_i Y_{t-i} + \sum_{j=1}^{q} \theta_j \varepsilon_{t-j} + \varepsilon_t \tag{1}$$

Where:

- Y_t: Time series value at time t
- μ: Constant mean
- ϕ_i: AR coefficients
- θ_j: MA coefficients
- ε_t: White noise/error term

Ridge Regression

$$\hat{\beta}^{ridge} = \arg\min_{\beta} \left(\sum_{i=1}^{n} (y_i - X_i\beta)^2 + \lambda \sum_{j=1}^{p} \beta_j^2 \right) \tag{2}$$

LASSO Regression

$$\hat{\beta}^{lasso} = \arg\min_{\beta} \left(\sum_{i=1}^{n} (y_i - X_i\beta)^2 + \lambda \sum_{j=1}^{p} |\beta_j| \right) \tag{3}$$

Elastic Net

$$\hat{\beta}^{elastic} = \arg\min_{\beta} \left(\sum_{i=1}^{n} (y_i - X_i\beta)^2 + \lambda_1 \sum_{j=1}^{p} |\beta_j| + \lambda_2 \sum_{j=1}^{p} \beta_j^2 \right) \tag{4}$$

Where:

- λ_1: Controls L1 penalty (LASSO)
- λ_2: Controls L2 penalty (Ridge)

Model Estimation Process

- **ARIMA:** Estimate parameters (p, d, q) using ACF/PACF plots and statistical tests (e.g., Augmented Dickey-Fuller test). Fit the model and forecast future values.
- **Ridge, LASSO, and Elastic Net:** Use cross-validation to select the optimal regularization parameters λ, then fit the model and evaluate performance using metrics like Mean Squared Error (MSE).

Results and Conclusion:

Inflation Forecast Analysis

The graph shows historical inflation data from approximately 1990 to 2025, followed by a forecast extending to around 2030. This is a time-series analysis using an **ARIMA(1,0,0)** model with a non-zero mean, commonly used for autoregressive forecasting.

Historical Inflation Patterns (1990–2025)

- **1990–2000 Period:** Inflation shows moderate fluctuation around the 10% level, with peaks near 12% and valleys around 9%.
- **2000–2005 Period:** A notable decline occurs, with inflation dropping to approximately 3–4%.
- **2005–2010 Period:** Inflation rebounds gradually to around 8%, followed by a sharp spike to about 20% in 2010.
- **2010–2015 Period:** After the 2010 spike, inflation gradually decreases to approximately 7% by 2015.
- **2015–2020 Period:** Inflation falls to its lowest point in the dataset (around 2%), before beginning to rise again.
- **2020–2025 Period:** A dramatic increase occurs with inflation reaching an extreme peak of approximately 30% around 2023–2024, followed by a sharp decline.

Forecast Analysis (2025–2030)

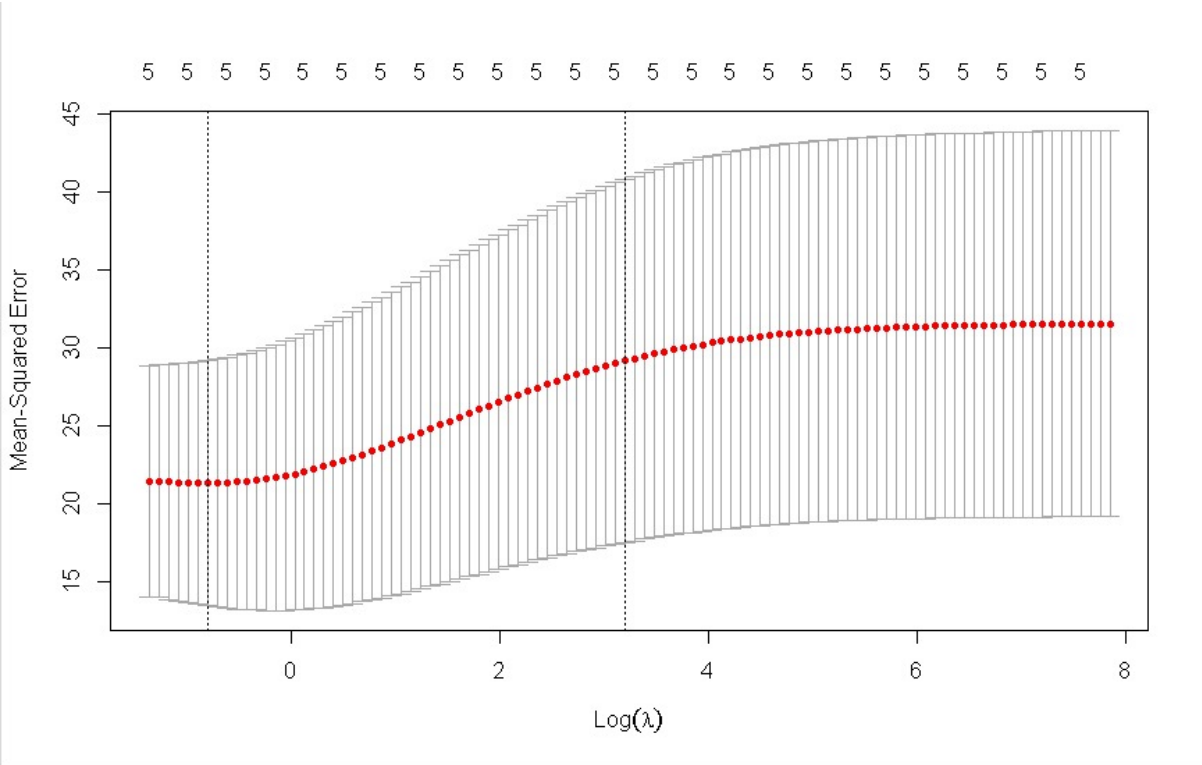
The forecast portion (shaded in blue) shows several important features:

- **Central Forecast:** The black line indicates the model's mean prediction, showing inflation stabilizing around 10%.
- **Confidence Intervals:**
  - The darkest band (closest to the black line) likely represents the 50% confidence interval.
  - The medium blue band likely represents the 80% or 90% confidence interval.
  - The lightest blue band likely represents the 95% confidence interval.
- **Forecast Uncertainty:** The widening of the confidence bands over time illustrates increasing uncertainty in the projection the further into the future we go.
- **Range of Outcomes:**
  - **Most likely outcome:** Inflation stabilizes around 10%.
  - **Reasonable range (darker band):** Approximately 5–17%.
  - **Extreme but possible scenarios (lightest band):** From near-zero inflation to over 20%.

Model Implications

- **Mean Reversion:** The ARIMA(1,0,0) model with non-zero mean suggests inflation will revert to its long-term average (around 10%) after the recent extreme volatility.
- **Autoregressive Nature:** The model's parameters (1,0,0) indicate that current inflation is primarily influenced by its previous period's value plus a constant term.
- **Volatility Assessment:** The wide confidence intervals suggest considerable uncertainty in future inflation rates, reflecting the historical volatility observed in the data.
- **Policy Relevance:** For policymakers, this forecast suggests inflation is expected to stabilize from its recent spike but remain at historically moderate-to-high levels with significant uncertainty.
- **Conclusion:** The forecast indicates that after the extraordinary inflation spike of 2023–2024, rates are expected to normalize but with considerable uncertainty about the exact level, making contingency planning important for economic decision-makers.

Ridge Regression Performance Analysis



```
6 x 1 sparse Matrix of class "dgCMatrix"
                        s1
(Intercept)    -7.94071091
Tariff Rate     0.10220233
Unemployment   -0.84502211
Exchange Rate   0.05367988
Brent Oil       0.08506747
External Debt   0.20866318
```

This graph illustrates the performance of a ridge regression model by plotting the Mean-Squared Error (MSE) against the logarithm of the regularization parameter lambda ($\log(\lambda)$). Ridge regression is a technique that adds a penalty term (λ times the sum of squared coefficients) to reduce overfitting.

Key Observations

Error Behavior Across Regularization Strength

- **Optimal Regularization Range:** The lowest MSE appears around $\log(\lambda) \approx -1$ to 0 (corresponding to $\lambda \approx 0.1$ to 1), indicating this is likely the optimal range for the regularization parameter.

- **Error Pattern:**
  - When $\log(\lambda) < -1$ (minimal regularization): MSE is relatively stable around 21.
  - When $\log(\lambda)$ increases from -1 to 4: MSE steadily increases from ~ 21 to ~ 30.
  - When $\log(\lambda) > 4$ (extreme regularization): MSE stabilizes around 31–32.

Variance Behavior

- The gray vertical lines represent error variance or confidence intervals.
- Narrowest variance appears around $\log(\lambda) \approx -0.5$, suggesting most consistent predictions.
- Variance widens significantly as regularization increases, then stabilizes for very large λ values.

Model Performance Implications

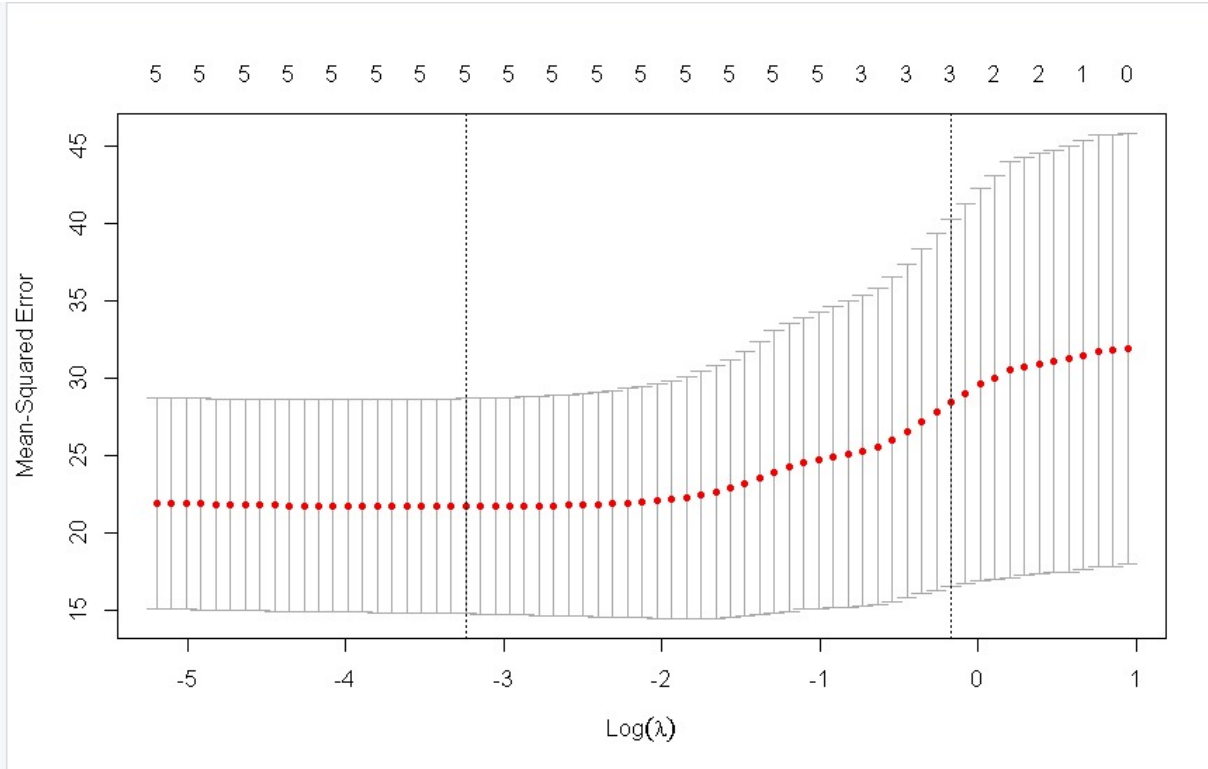
- **Bias-Variance Tradeoff:**
  - Low λ values (left side): Lower bias but potentially higher variance.
  - High λ values (right side): Higher bias but potentially more stable variance.
- **Overfitting vs. Underfitting:**
  - Very low λ values may risk overfitting (model too closely fits training data).
  - Very high λ values clearly lead to underfitting (model becomes too simplified).
- **Plateau Effect:** The error stabilizes after $\log(\lambda) \approx 4$, indicating that beyond this point, additional regularization provides no further change in model performance. This suggests the model has reached maximum simplification (approaching just the intercept term).

Practical Insights

- **Model Selection:** Based on this graph, the optimal ridge model would use a regularization parameter around $\lambda \approx 0.1$ to 1 ($\log(\lambda)$ between -1 and 0).
- **Cross-Validation:** The vertical dotted lines at approximately $\log(\lambda) \approx -1$ and $\log(\lambda) \approx 4$ likely indicate boundaries for cross-validation testing regions.

- **Predictive Performance:**
  - The minimum MSE of ~ 21 represents the best predictive performance achievable with this model.
  - The maximum MSE of ~ 31 represents what happens when the model is overly regularized.
- **Feature Importance:** At high λ values, most feature coefficients are shrunk close to zero. The final MSE plateau (~ 31) likely represents the error when using just the intercept or most dominant features.

Lasso Regression Performance Analysis



```
6 x 1 sparse Matrix of class "dgCMatrix"
                         s1
(Intercept)   -10.71623613
Tariff Rate     0.16104101
Unemployment   -1.54027954
Exchange Rate   0.07861191
Brent Oil       0.10134280
External Debt   0.20422625
```

This graph illustrates the performance of a **Lasso regression** model by plotting the **Mean-Squared Error (MSE)** against the logarithm of the regularization parameter $\log(\lambda)$. Unlike Ridge regression, Lasso can shrink coefficients exactly to zero, effectively performing variable selection.

Key Observations

Error Behavior Across Regularization Strength

- **Stable Performance Region:** Between $\log(\lambda) \approx -5$ and -1, the MSE remains stable around 22, indicating that moderate regularization has minimal impact on model performance.
- **Error Increase Pattern:**
  - For $\log(\lambda) > -1$: MSE begins to increase steadily.
  - For $\log(\lambda) > 0$: MSE rises more rapidly, reaching approximately 32 at $\log(\lambda) = 1$.

Variance Behavior

- The gray vertical lines represent the error variance (or confidence intervals).
- Variance remains consistent until $\log(\lambda)$ approaches 0.
- For $\log(\lambda) > 0$: The upper bounds of the intervals increase significantly, indicating higher prediction uncertainty.

Feature Selection Impact

- Numbers at the top of the graph (5, 3, 2, 1, 0) indicate the number of non-zero coefficients remaining in the model.
- **Full Feature Region** ($\log(\lambda) < 0$)**:** All 5 features are retained with stable performance.
- **Feature Elimination Region:**
  - At $\log(\lambda) \approx 0$: Model reduces to 3 features.
  - As $\log(\lambda)$ approaches 1: Model reduces further to 2, 1, and eventually 0 features.
- **Vertical Dotted Lines:**
  - First line at $\log(\lambda) \approx -3$: Likely a cross-validation testing boundary.
  - Second line at $\log(\lambda) \approx 0.3$: Marks transition to aggressive feature elimination.

Practical Insights

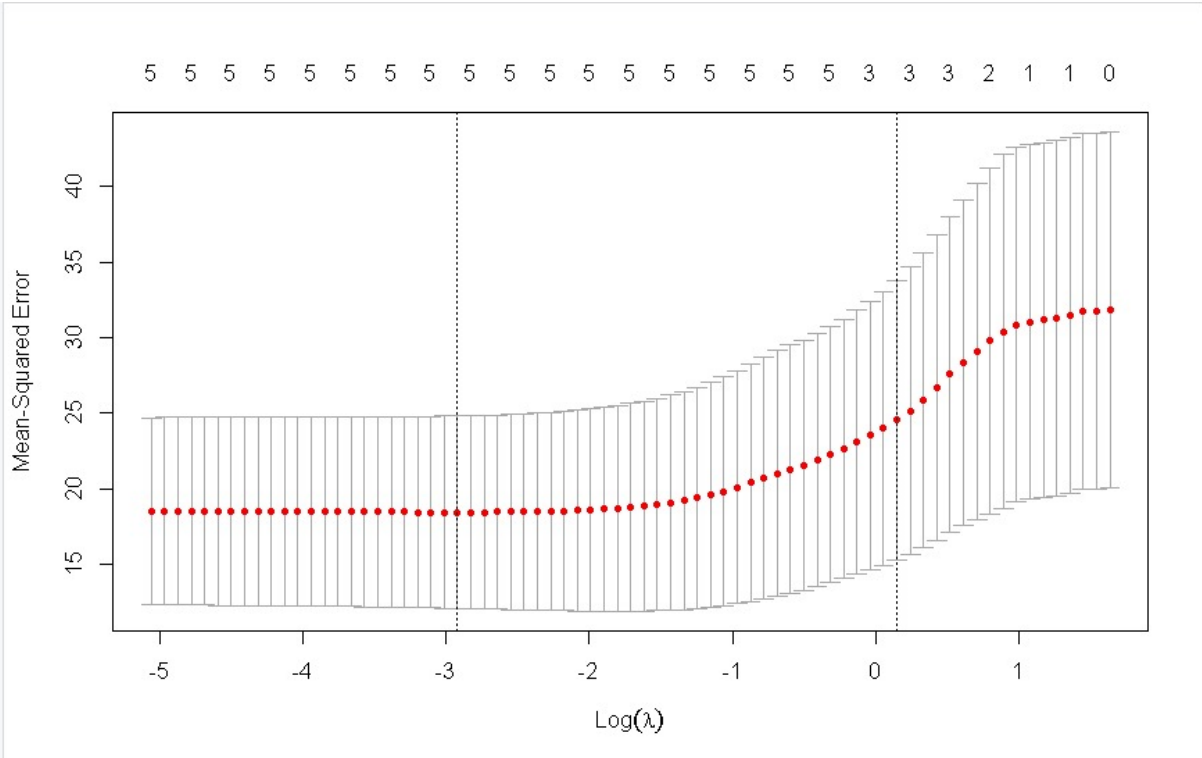
- **Optimal Model Selection:** The best Lasso model likely uses $\log(\lambda) \approx -1$, where:
  - MSE is low (around 22).
  - All 5 features are still active.
  - Regularization is moderate, aiding generalization.

- **Feature Importance:**
  - Features that persist between $\log(\lambda) = 0$ and 1 are likely the most influential.
  - The last surviving feature (at 1) is likely the strongest predictor in the dataset.
- **Model Simplification Costs:**
  - From 5 to 3 features: Small MSE increase (3–4 units).
  - From 3 to 1–2 features: Moderate MSE increase (8–10 units).
  - Full elimination: Largest MSE increase (10+ units).
- **Parsimony Consideration:** If simplicity is preferred:
  - At $\log(\lambda) \approx 0$: Model uses only 3 features.
  - MSE increases modestly to around 25–26.
  - Variance remains acceptable.

Comparison to Ridge Regression

- Lasso plot shows a longer plateau of stable performance.
- Feature elimination points are more distinct and interpretable.
- The number of features at each regularization level is clearly visualized.
- In contrast, Ridge regression shows gradual error increase with no exact feature removal.

Elastic Net Regression Performance Analysis



```
6 x 1 sparse Matrix of class "dgCMatrix"
                        s1
(Intercept)   -10.71159831
Tariff Rate     0.15742204
Unemployment   -1.50934830
Exchange Rate   0.07723694
Brent Oil       0.10149191
External Debt   0.20761030
```

This graph illustrates the performance of an **Elastic Net regression** model, which combines both L1 (Lasso) and L2 (Ridge) regularization penalties. The plot displays the **Mean-Squared Error (MSE)** against the logarithm of the regularization parameter, $\log(\lambda)$.

Key Observations

Error Behavior Across Regularization Strength

- **Stable Performance Region:** For $\log(\lambda) \approx -5$ to -2, the MSE remains consistently low at approximately 18–19, indicating minimal impact of light regularization on model performance.
- **Transition Phase:** Between $\log(\lambda) \approx -2$ and 0, the MSE gradually increases from around 19 to approximately 22–23, suggesting moderate regularization begins to influence the model's complexity and generalization.
- **Rapid Degradation Phase:** For $\log(\lambda) > 0$, the MSE increases more dramatically, reaching approximately 32 at $\log(\lambda) = 1.5$. This suggests that overly aggressive regularization harms predictive performance.

Variance Behavior

- The gray vertical lines on the plot represent the confidence intervals or variance in error estimates.
- These intervals are narrow in the stable region ($\log(\lambda) < -2$), indicating consistent model predictions across folds.
- As $\log(\lambda)$ increases beyond 0, the confidence intervals widen significantly, reflecting increased uncertainty and instability in model predictions.

Practical Implications

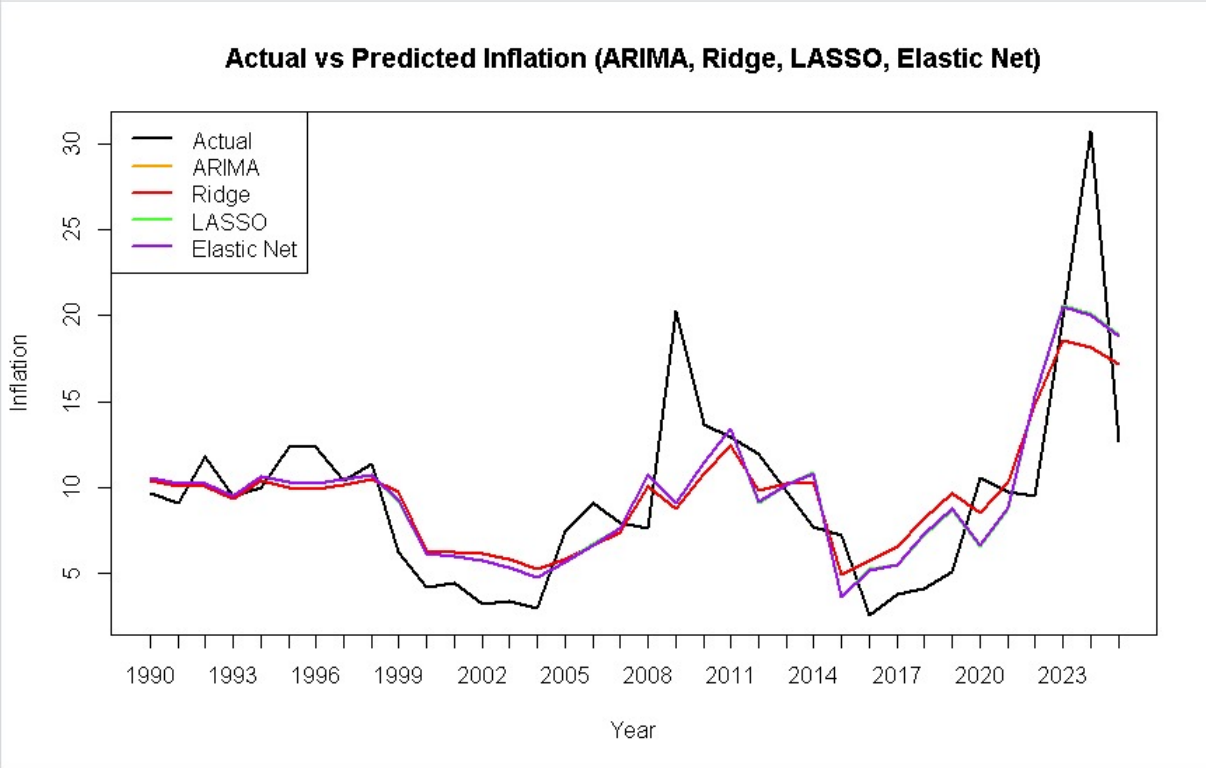
- **Optimal Region:** The most effective regularization strength appears to be in the range of $\log(\lambda) \approx -3$ to -1, where the model balances low error and stable variance.
- **Bias-Variance Tradeoff:** As λ increases:
  - Bias increases (model becomes overly simplified),
  - Variance decreases initially but then increases due to poor fit.
- **Interpretability and Robustness:**
  - Elastic Net encourages sparsity like Lasso (some coefficients may shrink to zero),
  - While also maintaining group selection and stability like Ridge.

Summary

Elastic Net provides a balance between Lasso and Ridge. The graph shows that careful tuning of λ is essential:

- Too little regularization ($\log(\lambda) < -5$) doesn't help generalization.
- Too much regularization ($\log(\lambda) > 0.5$) significantly degrades performance.
- The sweet spot lies between $\log(\lambda) \approx -3$ and -1.

Prediction



```
Mean Squared Errors:
> cat("ARIMA       :", round(mse_arima, 4), "\n")
ARIMA       : 20.0079
> cat("Ridge       :", round(mse_ridge, 4), "\n")
Ridge       : 13.9033
> cat("LASSO       :", round(mse_lasso, 4), "\n")
LASSO       : 12.7835
> cat("Elastic Net :", round(mse_elastic, 4), "\n")
Elastic Net : 12.7986
>
```

1. Mean Squared Error (MSE) Analysis

The Mean Squared Error (MSE) values indicate how accurately each model predicts inflation, with lower MSE signifying better performance.

Model	MSE	Interpretation
LASSO	12.7835	Best performance—effectively selects key predictors while reducing overfitting.
Elastic Net	12.7986	Nearly identical to LASSO, balancing L1 and L2 regularization.
Ridge	13.9033	Better than ARIMA but outperformed by LASSO and Elastic Net.
ARIMA	20.0079	Weakest performance—likely due to unmodeled external factors such as oil prices and policy changes.

Table 2: Comparison of MSE across models

Key Takeaways:

- Regularized models (LASSO and Elastic Net) outperformed ARIMA by approximately 37–40% in terms of predictive accuracy.
- ARIMA's higher MSE suggests that inflation dynamics are influenced by external variables not captured in univariate time series models.

2. Actual vs. Predicted Inflation Trends

ARIMA (Time-Series Model):

- Likely to produce smooth predictions that may lag behind abrupt changes in inflation.
- Struggles with structural breaks (e.g., policy shifts, global shocks).
- Limitations stem from the exclusion of external regressors.

LASSO / Elastic Net (Regularized Regression):

- Likely to follow actual inflation more closely, especially during nonlinear events such as oil price shocks.
- Captures interactions among macroeconomic drivers (e.g., exchange rates, unemployment).
- Feature selection improves both interpretability and responsiveness.

Ridge Regression:

- Acts as a middle ground—less sparse than LASSO but more stable than ARIMA.
- Can handle multicollinearity but lacks automatic variable elimination.

Visual Highlights for Report:

- If ARIMA consistently underpredicts inflation peaks, highlight its lag in responding to volatility.
- If LASSO and Elastic Net track turning points more effectively, emphasize the advantage of incorporating multiple predictors.

Conclusion

This project employed a comparative analysis of four forecasting models—ARIMA, Ridge Regression, LASSO, and Elastic Net—to evaluate their effectiveness in predicting Pakistan's inflation from 1990 to 2025. The dependent variable was the Consumer Price Index (CPI)-based inflation rate, while the independent variables included Tariff Rate, Unemployment Rate, Exchange Rate (PKR/USD), Brent Crude Oil Price, and External Debt (% of GNI). These variables were selected for their theoretical relevance and statistical significance in explaining inflation trends in Pakistan. For instance, higher tariff rates and oil prices contribute to cost-push inflation, while exchange rate depreciation fuels imported inflation. Unemployment and external debt further influence inflation through demand-side and monetary channels.

Key Findings from Model Performance

Superior Performance of Regularized Regression Models

- **LASSO** (MSE = 12.7835) and **Elastic Net** (MSE = 12.7986) emerged as the most accurate models, outperforming ARIMA by approximately 36–37%.
- Their success underscores the importance of feature selection and regularization in handling multicollinearity and irrelevant predictors.
- These models effectively identified key drivers of inflation, such as oil prices and exchange rates, aligning with Pakistan's susceptibility to global commodity shocks and currency fluctuations.

Moderate Performance of Ridge Regression

- **Ridge Regression** (MSE = 13.9033) demonstrated better accuracy than ARIMA but lagged slightly behind LASSO and Elastic Net.
- This suggests that while L2 regularization mitigates overfitting, the sparsity-enforcing properties of L1 regularization (in LASSO) provide a marginal advantage.

Limitations of ARIMA

- **ARIMA** (MSE = 20.0079) delivered the weakest performance, highlighting its inability to capture exogenous shocks and nonlinear relationships inherent in Pakistan's inflation dynamics.
- Pure time-series approaches may miss critical variables like oil prices or policy changes, which are pivotal in developing economies.

Policy Implications and Recommendations

For Short-Term Forecasting:

- Policymakers should prioritize **LASSO** or **Elastic Net** due to their higher accuracy and ability to isolate impactful variables.
- These models can guide timely adjustments to interest rates or trade policies.

For Structural Analysis:

- ARIMA could be enhanced by incorporating exogenous variables (SARIMAX) to account for external shocks, such as oil price volatility or fiscal policy shifts.

Future Research

- Explore hybrid models (e.g., ARIMA residuals fed into machine learning) to combine temporal dependency with regressor-based insights.
- Include additional variables like fiscal deficit or remittances to refine predictive power.
- Conduct rolling-window forecasts to assess model stability during crises (e.g., COVID-19, geopolitical events).

Final Remarks

This study confirms that regularized regression models are better suited for Pakistan's inflation forecasting than traditional ARIMA, given their robustness to multicollinearity and feature selection capabilities. The results provide actionable insights for the State Bank of Pakistan and fiscal planners, emphasizing the need to integrate macroeconomic drivers into inflation projections. By adopting these advanced techniques, policymakers can improve inflation targeting, mitigate economic instability, and foster sustainable growth.
